Abstract

We introduce an incentive mechanism to elicit answers to binary questions that cannot be verified for accuracy. Agents choose whether to receive a costly private signal, which leads them to endorse "yes" or "no" as an answer. Then, they either buy or sell an asset, whose value is determined by the endorsement rate of "yes" answers. We obtain a separating equilibrium, where agents want signals and trade the asset as a function of their signal. Two experimental studies test the theoretical results. The first shows that the mechanism motivates costly information acquisition. The second demonstrates feasibility in a natural setting.

1 Introduction

"Have you stood less than 6 feet apart from another person in a queue yesterday?" Health surveys often require respondents to recollect past experiences. This experience can be seen as a private signal that respondents acquire by exerting effort (recalling, to their mind, what they did a day earlier.) But how can we ensure that the respondents will, first, provide such effort and then, answer accurately if there is no way to compare their answer to some ground truth?

Starting with Crémer and McLean (1988), the mechanism design literature has explored ways to reveal private signals. Miller et al. (2005), and more broadly the peer-prediction literature (Witkowski and Parkes, 2012a, 2013; Liu and Chen, 2017a), have proposed solutions 10 exploiting the informativeness of a respondent's answer in predicting their peers' answers. 11 For instance, imagine that we have some prior expectations about the rate of yes answers 12 to the 6-feet-apart question. A respondent answering yes increases our expectations about 13 the proportion of other people answering yes. Formally, this increase is a simple applica-14 tion of Bayesian updating when respondents draw a private signal (yes/no), with unknown 15 probability p of yes signals: a yes signal makes higher values of p more likely than initially 16 believed. Intuitively, the ves answer to the 6-feet-apart question can suggest that others also had difficulty complying with a social distancing guidelines. 18

In this paper, we propose and implement a novel solution to incentivize private signals acquisition and revelation: a peer-prediction market (PPM). In a PPM, yes respondents are rewarded with the formula "yes answer rate - prior expectations of yes answer rate". Those who answer no get the opposite reward. If there are fewer yes answers than expected, yes respondents get a negative reward while no respondents get a positive one. Equivalently, a PPM can be presented as yes (no) respondents buying (selling) a single asset, the value of which is eventually determined by the proportion of yes answers. The price is set to the prior

 $^{^{1}}$ We assume here that signals are conditionally independent, i.e. independent given the probability of success. The probability of success is assumed to be itself drawn from a non-degenerate distribution over (0,1).

expectations. In a situation in which the yes-answer rate is expected to follow a random walk, a repeated PPM can be implemented in which the price at period t is the value of the asset at t-1.

First, we show that signal acquisition and revelation is a Bayesian Nash equilibrium, providing a partial-implementation solution to the static problem. Our solution is minimal, in the sense that it does not ask respondents to provide more than their answer and it does not require the surveyor to share more than prior expectations with the respondents. We then extend our analysis to incorporate psychological costs, capturing the possible (mild) discomfort of reporting an answer and potential deception costs.

Second, we test PPM in an online experiment closely following the theoretical model: respondents may exert an effort (i.e., complete a real-effort task borrowed from the experimental economics literature) to obtain a signal and report the beliefs they derive from it; or they may simply answer randomly. We compare PPM with two benchmarks: flat fee (no incentives) and accuracy incentives (incentives when the signal generation process is observable). The latter is not applicable in surveys, where such process in unobservable but it provides a gauge for the effect of PPM. In our experiment, a flat fee decreases the effort rate by about 20 percentage points with respect to accuracy incentives. PPM allows us to recover half of this difference.

Third, we demonstrate feasibility in a natural setting. We implement the repeated PPM in the context of a health survey, involving questions of the 6-feet-apart type. The asset price is set to the previous week yes-rate. We hypothesize that people not exerting recollection efforts or feeling some slight discomfort for not complying with health guidelines are likely to deny having experienced such situation, and therefore that PPM will trigger higher rate of yes answers than a flat fee. We indeed obtain that more people admit experiencing situations in contradictions with health guidelines in the PPM treatment than in the flat fee treatment. This second study shows that PPM can be applied to socially relevant questions, where psychological costs of reporting non-compliance may be present.

Related literature - PPMs relates to the mechanism design literature starting with Myerson (1986) and (Crémer and McLean, 1988).² This strand of literature built signal revelation
mechanism exploiting between-agent signal correlation. As in Myerson (1986), signal revelation in our paper is not the only equilibrium, which is known as partial implementation (see
for instance Maskin (1999) for an example of full implementation that excludes undesirable
equilibria).

PPMs offer a market-based solution to the problem of incentivizing effort in information elicitation without verification (Waggoner and Chen, 2013). Previous work introduced peer prediction mechanisms that consider the signal revelation problem only, and does not explicitly model costly signal acquisition. The original peer prediction method (Miller et al., 2005) can be adjusted for costly effort via re-scaling of payments. PPMs are more transparent than typical peer prediction methods (Miller et al., 2005; Witkowski and Parkes, 2012a, 2013; Liu and Chen, 2017a), which used scoring rules instead of simple trades. The present paper is also the first of this stream of literature to include both cost of efforts and psychological costs in the model.

The PPM method relaxes the typical common prior assumption made, for instance, by Miller et al. (2005), by requiring agents to share their prior *expectation*, instead of the full prior. Weakening beliefs assumptions is central in the literature on (partial or full) implementation (Bergemann and Morris, 2005, 2009a,b). A mechanism is more robust if it provides incentive compatibility for a larger set of beliefs (Ollár and Penta, 2017, 2019).

Follow-up work developed peer prediction mechanisms for effort elicitation in crowdsourcing problems with unverifiable tasks, such as peer grading, content classification etc.
Witkowski et al. (2013) study output agreement mechanisms, in which agents receive positive payment if their reports agree with their peers'. Simple output agreement mechanisms
do not achieve signal revelation when an agent believes to hold a minority signal, which may
also affect effort decision. PPMs do not have this problem.

 $^{^{2}}$ In that, we differ from the (Bayesian) information design literature, where the payoff structure is fixed (Kamenica, 2017, 2019).

Methods to elicit private signals face the tradeoff between minimality (Witkowski and Parkes, 2012a), i.e. asking only one question as we do, and being detailed-free, i.e. not requiring specific knowledge from the center, to follow the desiderata of the Wilson doctrine (Wilson, 1987). Peer prediction methods choose minimality. By contrast Bayesian truth serum (Prelec, 2004) and its variants (Witkowski and Parkes, 2012b; Radanovic and Faltings, 2013, 2014) are detail-free. They do not require any knowledge of the prior. However, respondents are asked to provide some information about it on top of their answers. Cvitanić et al. (2019) proposes the most general form, even replacing the additional information about prior by another verifiable question. All these mechanisms are however not minimal and theorefore more demanding to respondents than PPMs.

Closest to PPMs, but also not minimal, are Bayesian markets (Baillon, 2017), which provide a market solution to binary elicitation problems in a similar Bayesian setup to ours, except that information is not costly. Moreover, unlike PPM, agents first report their answers, which determines whether they can buy or sell an asset defined as in PPMs. Then a price is determined randomly and the agents must decide whether to actually trade at this price. In equilibrium, agents report their private signal to be eligible for their desired trade. In the way they are set-up, PPMs aim to be closer to prediction markets than Bayesian markets are. The price is pre-specified and agents make only one buy-or-sell decision.

Settings with multiple, correlated questions allow for minimal and detail-free methods. 97 Dasgupta and Ghosh (2013) use reports in multiple auxiliary questions to penalize agreement without effort in a binary question of interest. Shnayder et al. (2016) generalize Dasgupta and Ghosh (2013) to obtain correlated agreement mechanism for non-binary questions and 100 Baillon and Xu (2021) simplifies the method using bets. Correlated agreement uses multiple 101 questions and requires specific assumptions about correlations across questions or shared sig-102 nal technology, which PPMs do not require. Peer truth serum for crowdsourcing is another 103 peer agreement mechanism which uses agents' responses to multiple questions Radanovic 104 et al. (2016). Liu and Chen (2017b) develop sequential peer prediction, in which agents 105

submit answers sequentially and the mechanism learns the optimal reward for effort elicitation over time. Sequential peer prediction is minimal, but unlike PPM, requires a dynamic
setup. In binary elicitation problems, PPM offers a simpler minimal alternative to other peer
prediction mechanisms to incentivize signal acquisition and revelation, which also works in
one-shot problems.

111 2 Theory

112 2.1 Agents and their information

A center (a researcher, a survey company) is interested in eliciting N agents' informed 113 answers to a question Q, with possible answers $\{0,1\}$. Agents can answer randomly at 114 no cost but they may also decide to provide an effort (thinking, remembering, looking for 115 information, etc.) to obtain their informed answer. Formally, agent $i \in \{1, \ldots, N\}$ can 116 obtain a signal $s_i \in \{0,1\}$ by providing effort $e_i = 1$ at a cost $c_i > 0$ (expressed in monetary 117 terms). The cost of no effort $(e_i = 0)$ is 0. There are two possible interpretations for s_i . It 118 is either directly the informed answer to the question (agent i remembers what happened) 119 or a signal that unequivocally influences the agent's opinion about the correct answer, i.e., 120 signal 1 leads the agent to believe that answer 1 is correct and signal 0 induces the opposite 121 belief. To keep notation minimal, we do not formally differentiate between signals and signal-122 induced beliefs. As usual in this literature (e.g., Prelec, 2004; Miller et al., 2005), we assume 123 that the probability of getting signal 1 is the same for all agents (hence, it is independent of 124 the effort cost) but is unknown. We model it as a random variable ω over [0, 1]. Denoting 125 $s = (s_1, \ldots, s_N)$, a state of nature is thus a realization of ω and s, with the state space being $\Omega = [0,1] \times \{0,1\}^N$. The probability space is (Ω, Σ, P) , with Σ the Borel σ -algebra of Ω 127 and we assume that P is countably additive. The next assumption describes the full signal 128 technology. 129

Assumption 1 (Signal technology). The signal technology is such that for all $i, j \in \{1..., N\}$,

131 $i \neq j$, and $o \in [0, 1]$:

132 1.
$$P(s_i = 1 | \omega = o) = o;$$

133 2.
$$P(s_i = 1 | s_j, \omega = o) = o;$$

3. and $P(\omega)$ is continuous over [0,1].

Part 1 of Assumption 1 states that the signal technology is anonymous, part 2 that it satisfies conditional independence, and part 3 that no value of ω has a probability mass. The latter excludes degenerate cases in which all agents could get the same signal for sure or in which ω would be known.

Let P_i represent the belief of agent i about the signal technology, and P_0 that of the center. It is common to assume $P_i = P_0 = P$ in peer prediction mechanisms.³. We allow agents to have different opinions on how likely various values of ω are but the following assumption restrict their belief in two ways.

Assumption 2 (Unbiased prior expectations). For all $i \in \{0, ..., N\}$, P_i satisfies properties

1-3 of Assumption 1 and $E_i(\omega) = E(\omega)$.

Assumption 2 states that all agents and the center agree on the main properties of the 145 signal technology and share the same prior expectation. It is a strong assumption, despite 146 relaxing the often-used common prior assumption. Assumption 2 is plausible if (i) question 147 Q is new and people have no reason to believe that answer 1 is more likely than answer 0, i.e., 148 $E(\omega) = 0.5$; or (ii) signals of another group of agents have been publicly revealed (possibly 149 with another mechanism); or (iii) the agents have no clue about ω but the center shares 150 its prior expectation. In case (i), we do not need to assume uniform P_i over the possible 151 values of ω ; e.g., it can be bell-shaped for some agents. Case (ii) can correspond to situations 152 in which question Q was asked in the past (to other agents) but the center and the (new)

 $^{^3}$ Or $P_i = P$ with no assumption on P_0 in the Bayesian truth-serum of (Prelec, 2004) or Bayesian markets of (Baillon, 2017)

agents do not know whether the signal distribution will be exactly the same. For instance, imagine that, a month ago, it was published that 73% of people reported they could always stay 6 feet away from others. There are many reasons why this proportion might change but before agents try to remember their own experience, 73% is a good average guess about what others will answer. Case (iii) may occur when the center has the means to study the signal technology; for instance, a review website where people report their (binary) experience with hotels or movies can study signal distribution and display prior average expectation. Let us denote $\bar{\omega} \equiv E(\omega)$, $\bar{\omega}_i^0 \equiv E_i(\omega|s_i=0)$ and $\bar{\omega}_i^1 \equiv E_i(\omega|s_i=1)$.

Lemma 1. Under Assumptions 1 and 2, for all $i \in \{1, ..., N\}$, $0 < \bar{\omega}_i^0 < \bar{\omega} < \bar{\omega}_i^1 < 1$.

163 *Proof.* First part 3 of Assumption 1 excludes $\bar{\omega} \in \{0, 1\}$.

Second, $P_i(s_i = 1) = \int_0^1 P_i(s_i = 1 | \omega = o) \times P_i(\omega = o) do = \int_0^1 o \times P_i(\omega = o) do = E_i(\omega) = 165$ $\bar{\omega}$. $\bar{\omega}_i^1 = \int_0^1 \frac{P_i(s_i = 1 | \omega = o) \times P_i(\omega = o) \times o}{P_i(s_i = 1)} do = \int_0^1 \frac{o^2 \times P_i(\omega = o)}{\bar{\omega}} do > \bar{\omega}$ because $\int_0^1 o^2 \times P_i(\omega = o) > 166$ $\left(\int_0^1 o \times P_i(\omega = o)\right)^2 = \bar{\omega}^2$ by Jensen's inequality applied to the convex squared function and 167 the inequality is strict because we degenerate cases were excluded by Part 3 of Assumption 1, 168 which also excludes a posterior expectation of 1. The proof of $0 < \bar{\omega}_i^0 < \bar{\omega}$ is symmetric. \square

Lemma 1 shows that under our assumptions, all agents receiving signal 1 have higher expectations about ω than they had ex ante (and than the center) whereas agents with signal 0 decrease their expectations. Finally, we make the following assumption on agents' risk preferences:

Assumption 3 (Risk neutrality). Agents are risk neutral.

Assumption 3 implies that agents maximize their expected payoffs. Section 2.2 introduces a market mechanism to exploit the difference in expectations established in Lemma 1. Assumption 3 suggests that agents' optimal strategy will not depend on a risk parameter.

177 2.2 The Market

The center implements a peer-prediction market for Q, in which an asset is traded whose value will be the proportion of agents reporting 1 as answer for Q multiplied by π , a scaling constant. If the currency is the dollar, $\pi = 10$ means that the asset is worth \$5 if 50% of the agents report 1.

Definition 1. A peer-prediction market is defined by the following steps:

- 183 1. The center announces the asset price $\bar{\omega}\pi$.
- 2. Agents simultaneously choose a report $r_i \in \{0,1\}$. Those who report 1 become buyers of the asset and those who report 0 become sellers.
- 3. The center computes the asset value $\bar{r}\pi = \frac{\pi}{N} \sum_{i=1}^{n} r_i$.
- 4. If $\bar{r} = 0$ or $\bar{r} = 1$, the market is stopped; no payment occurs.
- 5. Otherwise, buyers pay $\bar{\omega}\pi$ to the center in exchange of $\bar{r}\pi$ and sellers receive $\bar{\omega}\pi$ from the center in exchange of $\bar{r}\pi$.

In a peer-prediction market, reporting a 1 answer $(r_i = 1)$ is equivalent to betting that 190 the proportion of 1 answers will be higher than $\bar{\omega}$, that is, buying the asset. Symmetrically, 191 reporting a 0 answer is a bet on a proportion of 1 answers lower than $\bar{\omega}$. Step 5 specifies that 192 all trades are made with the center, and not directly between agents. Direct trading would 193 lead to complications such as the no-trade theorem (Milgrom and Stokey, 1982): knowing 194 that someone wants to sell informs the buyer that someone received a 0 signal, and conversely. 195 Ultimately, agents who report 1 get $(\bar{r} - \bar{\omega})\pi$ and those who report 0 get $(\bar{\omega} - \bar{r})\pi$. The 196 center subsidies the market if need be. The agents subtract c_i from their earnings if they 197 provided an effort. 198

2.3 Strategies and Equilibria

The agents' strategies in the peer-prediction market involve first deciding whether to exert an effort, and then what to report. We will consider mixed strategies only in reports, so agent i's strategy is given by (e_i, R_i, R_i^0, R_i^1) with R_i , R_i^0 , and R_i^1 the probabilities of $r_i = 1$ if $e_i = 0$, if $e_i = 1$ and $s_i = 0$, and if $e_i = 1$ and $s_i = 1$ respectively. The strategy space is thus $\{0, 1\} \times [0, 1]^3$. The center is interested in situations in which agent i exerts an effort and reveals s_i , i.e., $e_i = 1$, $R_i^0 = 0$, and $R_i^1 = 1$. We need to make one final assumption, about what agents know about each others.

Assumption 4 (Common knowledge). The peer-prediction market functioning, the strategy space, the signal technology, the beliefs P_i , the costs c_i and agents' risk neutrality are common knowledge.

Assumption 4 ensures that we have specified all the elements of a *Bayesian game*, as defined by (Osborne and Rubinstein, 1994, Definition 25.1). If beliefs and costs were not common knowledge, we would have to define higher-order beliefs, which would complicate the proofs. As we will see below the crucial part is not so much that agents know the exact beliefs of everyone, but rather that all agents know that Lemma 1 holds. Again for convenience, we let $N \to \infty$. It allows us to assimilate signal probability with signal proportion. It also allows us to neglect the impact of a single agent on the asset value.

Proposition 1. Under Assumptions 1 to 4 and with N infinite, if $c_i > \pi$ for all $i \in \{1, ..., N\}$, then Nash equilibria are characterized by $e_i = 0$ and $R_i \in \{0, \bar{\omega}, 1\}$. Expected payoffs are 0.

Proof. Possible earnings $(\bar{r} - \bar{\omega})\pi$ and $(\bar{\omega} - \bar{r})\pi$ are both strictly lower than π , and therefore than c_i if $c_i > \pi$. There are no incentives to provide efforts; hence, $e_i = 0$. Consider agent i and assume all other agents $j \neq i$ have the same probability to report 1 $(R_j = R)$ for some $R \in [0,1]$. Hence, with R = 1 in a set value $\bar{r} = 1$ is optimal. If $R \in [0,\bar{\omega})$, $R \in [0,1]$ is optimal. If $R \in [0,\bar{\omega})$,

then $R_i = 0$ is optimal. Finally, if $R = \bar{\omega}$, then any $R_i \in [0, 1]$ is optimal. Nash equilibria require $R_i = R$ such that no one has incentives to deviate. Hence, we must have either $R_i = 1$ for all i, or $R_i = 0$ for all i, or $R_i = \bar{\omega}$ for all i. In all these cases, earnings are 0 (remember that if $\bar{r} = 0$ or 1, no payoffs occur as specified in step 4 of Definition 1.

Proposition 1 highlights three equilibria in which agents make no efforts. In two of these equilibria, they all report the same answer, either 0 or 1. In the third equilibrium, the probability to report 1 is equal to the prior probability. Study 1 will explore what agents do when they decide not to get a signal.

Proposition 2. Under Assumptions 1 to 4 and with N infinite, if for all $i \in \{1, ..., N\}$ $\frac{c_i}{\pi} < \bar{\omega} \times (\bar{\omega}_i^1 - \bar{\omega}) + (1 - \bar{\omega})(\bar{\omega} - \bar{\omega}_i^0)$, acquiring and revealing signals $(e_i = 1, R_i^0 = 0, and$ $R_i^1 = 1$ is a Nash equilibrium, and it strictly dominates the no-effort equilibria.

Proof. Let us consider agent i's view point and assume $e_j = 1$, $R_j^0 = 0$, and $R_j^1 = 1$ for all $j \neq i$. Without any signal, agent i's expected earnings are $[R_i(E_i(\omega) - \bar{\omega}) + (1 - R_i)(\bar{\omega} - E_i(\omega))]$ $\times \pi = 0$ by Assumption 2.

With signal 1, agent *i*'s expected earnings are $[R_i^1(\bar{\omega}_i^1 - \bar{\omega}) + (1 - R_i^1)(\bar{\omega} - \bar{\omega}_i^1)] \times \pi$. By Lemma 1, this is maximum for $R_i^1 = 1$, yielding $(\bar{\omega}_i^1 - \bar{\omega}) \times \pi > 0$.

With signal 0, agent *i*'s expected earnings are $[R_i^0 (\bar{\omega}_i^0 - \bar{\omega}) + (1 - R_i^0) (\bar{\omega} - \bar{\omega}_i^0)] \times \pi$. By
Lemma 1 again, this is maximum for $R_i^0 = 0$, yielding $(\bar{\omega} - \bar{\omega}_i^0) \times \pi > 0$.

Before getting a signal, the expected gain is therefore,

$$\left[P_i(s_i=1) \times \left(\bar{\omega}_i^1 - \bar{\omega}\right) + P_i(s_i=0) \left(\bar{\omega} - \bar{\omega}_i^0\right)\right] \times \pi = \left[\bar{\omega} \times \left(\bar{\omega}_i^1 - \bar{\omega}\right) + (1 - \bar{\omega}) \left(\bar{\omega} - \bar{\omega}_i^0\right)\right] \times \pi.$$

This is strictly positive by construction and strictly more than c_i by assumption. Hence, the net earnings (once the costs are subtracted) are strictly positive and providing an effort is worth it. As a consequence, $e_i = 1$, $R_i^0 = 0$, and $R_i^1 = 1$ is a Nash equilibrium.

Finally, let us consider the case in which all agents but i provide no efforts and report 1

with probability R. The expected earnings are

$$\begin{cases} [R_i^1 \times (R - \bar{\omega}) + (1 - R_i^1) \times (\bar{\omega} - R)] \times \pi & \text{with signal 1} \\ [R_i^0 \times (R - \bar{\omega}) + (1 - R_i^0) \times (\bar{\omega} - R)] \times \pi & \text{with signal 0} \\ [R_i \times (R - \bar{\omega}) + (1 - R_i) \times (\bar{\omega} - R)] \times \pi & \text{with no signal.} \end{cases}$$

As in Proposition 1, the only equilibria must be of the form $R_i = R \in \{0, \omega, 1\}$, and by similar arguments $R_i^1 = R_i^0 = R \in \{0, \omega, 1\}$. The earnings are always 0 and the net earnings with effort are even strictly negative. Hence, $e_i = 0$, $R_i \in \{0, \omega, 1\}$ is also a Nash equilibrium (with $R_i^1 = R_i^0 = R_i$) but it is dominated by the equilibrium with signal acquisition and revelation ($e_i = 1$, $R_i^0 = 0$, and $R_i^1 = 1$).

In Proposition 2, the effort cost is lower than the expected gain of signal acquisition and revelation for all agents, while it was too high in Proposition 1. Intermediary situations are addressed in the following propositions.

Proposition 3. Under Assumptions 1 to 4 and with N infinite, if for $T \times 100\%$ of the agents $\frac{c_i}{\pi} > \bar{\omega} \times (T\bar{\omega} + (1-T)\bar{\omega}_i^1 - \bar{\omega}) + (1-\bar{\omega})(\bar{\omega} - T\bar{\omega} - (1-T)\bar{\omega}_i^0)$ and the inequality is reversed for the remaining agents, then there is a Nash equilibrium in which these $T \times 100\%$ will exert no efforts and report 1 with probability $\bar{\omega}$ and where the other agents acquire and reveal their signals.

Proof. First, let us assume that all agents but i play the strategy described in the proposition.

With signal 1, agent i expects the asset value to be $T\bar{\omega} + (1-T)\omega_i^1$, and with signal 0

 $T_{\bar{\omega}} = T_{\bar{\omega}} + (1-T)\omega_i^0$. By Lemma 1, $T_{\bar{\omega}} + (1-T)\omega_i^0 < \bar{\omega} < T_{\bar{\omega}} + (1-T)\omega_i^1$, and with the same

argument as in the proof of Proposition 2, it is best to reveal signals, $R_i^0 = 0$ and $R_i^1 = 1$.

Ex ante, the expected benefit of exerting an effort is therefore

$$[\bar{\omega} \times (T\bar{\omega} + (1-T)\bar{\omega}_i^1 - \bar{\omega}) + (1-\bar{\omega})(\bar{\omega} - T\bar{\omega} - (1-T)\bar{\omega}_i^0))]\pi - c_i.$$

If
$$\frac{c_i}{\pi} \leq \bar{\omega} \times (T\bar{\omega} + (1-T)\bar{\omega}_i^1 - \bar{\omega}) + (1-\bar{\omega})(\bar{\omega} - T\bar{\omega} - (1-T)\bar{\omega}_i^0)$$
 then $e_i = 1$ is optimal.

If $\frac{c_i}{\pi} > \bar{\omega} \times (T\bar{\omega} + (1-T)\bar{\omega}_i^1 - \bar{\omega}) + (1-\bar{\omega})(\bar{\omega} - T\bar{\omega} - (1-T)\bar{\omega}_i^0)$, an effort leads to negative net earnings, whereas exerting no efforts gives $[R_i \times (T\bar{\omega} + (1-T)E_i(\omega) - \bar{\omega}) + (1-R_i)(\bar{\omega} - T\bar{\omega} - (1-T)E_i(\omega))]\pi = 0 \text{ because of the}$ common prior expectations assumption. Hence, $e_i = 0$ and $R_i = \bar{\omega}$ is a best response in this case.

In the equilibrium of Proposition 3, the proportion T of agents not providing an effort have negative externalities on others by decreasing the extent to which the asset value can differ from the prior expectations. This reduces the value of providing an effort for everyone.

2.4 Psychological costs

So far, we have only considered effort costs. In this subsection, two additional costs are considered:

- Asymmetric reporting cost: Sometimes, one answer may be slightly stigmatizing, regardless of the truth, for instance admitting not compliance with guidelines. We model this as a cost $a_i \geq 0$ borne by agent i when reporting $r_i = 1$ per se, no matter whether the agent receives a signal and what this signal may be. We choose 1 arbitrarily, and without loss of generality. This cost can reflect a stigma associated with answer 1. As we will see in the theoretical results and later in the experimental applications, a_i should not be too high, thereby excluding major incentives to lie. However, a_i can arise from social desirability bias (Tourangeau and Yan, 2007), including descriptive (what behaviours are common) and injunctive norms (what behaviours are acceptable).
- Deception cost: The cost $d_i \geq 0$ of reporting $r_i = 0$ after receiving signal $s_i = 1$ or reporting $r_i = 1$ after receiving signal $s_i = 0$. This cost captures people's preference to tell the truth, as shown by Abeler et al. (2019) and also known in psychology as the Truth-Default Theory (Levine et al., 2010; Levine, 2014). People are averse towards lying about private information (Lundquist et al., 2009). Moreover lying tends to

be more cognitively demanding, leading to increased reaction times (Suchotzki et al., 2017), and negatively affecting people's self-concept (Mazar et al., 2008). We assume that such costs can only occur when a signal has been received because cost for reporting an answer in spite of having no signal would be equivalent to decreasing the effort costs.

Assumption 5. Agents bear asymmetric reporting costs $a_i \geq 0$ and deception costs $d_i \geq 0$ and these costs are common knowledge.

Proposition 4. Under Assumptions 1 to 5 and with N infinite, if for all $i \in \{1, ..., N\}$ $\frac{c_i}{\pi} < \bar{\omega} \times \left(\bar{\omega}_i^1 - \bar{\omega} - \frac{a_i}{\pi}\right) + (1 - \bar{\omega})\left(\bar{\omega} - \bar{\omega}_i^0\right) \text{ and } \frac{a_i}{\pi} < \frac{d_i}{\pi} + 2\left(\bar{\omega}_i^1 - \bar{\omega}\right), \text{ signal acquisition and}$ revelation $(e_i = 1, R_i^0 = 0, \text{ and } R_i^1 = 1)$ is a Nash equilibrium, and it strictly dominates the no-effort equilibrium.

Proof. Let us consider agent i's view point and assume $e_j = 1$, $R_j^0 = 0$, and $R_j^1 = 1$ for all $j \neq i$. Without any signal, agent i's expected earnings are

$$\left[R_i\left(E_i(\omega) - \bar{\omega} - \frac{a_i}{\pi}\right) + (1 - R_i)\left(\bar{\omega} - E_i(\omega)\right)\right] \times \pi \le 0.$$

With signal 1, agent i's expected earnings are

$$\left[R_i^1\left(\bar{\omega}_i^1 - \bar{\omega} - \frac{a_i}{\pi}\right) + (1 - R_i^1)\left(\bar{\omega} - \bar{\omega}_i^1 - \frac{d_i}{\pi}\right)\right] \times \pi - c_i.$$

This is maximum for $R_i^1=1$, because $\frac{a_i}{\pi}<\frac{d_i}{\pi}+2\left(\bar{\omega}_i^1-\bar{\omega}\right)$. With signal 0, agent *i*'s expected earnings are

$$\left[R_i^0 \left(\bar{\omega}_i^0 - \bar{\omega} - \frac{a_i}{\pi} - \frac{d_i}{\pi}\right) + (1 - R_i^0) \left(\bar{\omega} - \bar{\omega}_i^0\right)\right] \times \pi - c_i.$$

This is maximum for $R_i^0 = 0$. Before getting a signal, the expected payoff is therefore, $[\bar{\omega} \times (\bar{\omega}_i^1 - \bar{\omega} - \frac{a_i}{\pi}) + (1 - \bar{\omega})(\bar{\omega} - \bar{\omega}_i^0)] \times \pi - c_i$. This is strictly positive by assumption.

Hence, providing an effort is worth it. As a consequence, $e_i = 1$, $R_i^0 = 0$, and $R_i^1 = 1$ is a Nash equilibrium.

Finally, let us consider the case in which all agents but i provide no efforts and report 0 306 (as in Proposition 1). The best agent i can do is to provide no effort and report 0 as well, 307 yielding expected earnings 0, which is dominated by signal acquisition and revelation. 308 Proposition 4 establishes two sufficient conditions for the existence of an equilibrium in 309 which signals are acquired and revealed. The first one, as in Proposition 2, ensures that the 310 expected payoffs with effort is higher than with no effort. The second one ensures that the 311 cost of reporting the stigmatizing answer does not exceed the benefit of truthfully revealing 312 one's signal. This benefit is twofold: the agent does not lie (so no deception costs d_i) and buys 313 the asset instead of having to sell it. This leads to three remarks. First, costs of reporting a 314 stigmatizing answers are moderated by the cost of lying. Second, if $\frac{a_i}{\pi} > \frac{d_i}{\pi} + 2(\bar{\omega}_i^1 - \bar{\omega})$, the 315 corresponding agent will anticipate to never report 1 anyhow and therefore, has no incentives 316 to provide an effort. In other words, in our model, conscious lying has no reason to occur 317 because agent will simply prefer not to get a signal and report the more acceptable answer. 318 Third, a higher π is useful to both stimulate effort and reduce incentives to lie. 319

320 3 Experimental Evidence

Section 2 established the existence of an equilibrium where agents in a PPM seek costly information and make informed trades. Agents' incentives in trading are based on their peers' behavior, as value of the asset is determined by other agents' trades. Are such peer-based incentives effective in eliciting effort in practice? This section presents evidence from two experimental studies. Section 3.1 provides a brief overview of the two studies and the findings. Sections 3.2 and 3.3 provide detailed information on the two studies and present the results.

$_{28}$ 3.1 Overview

We run two experimental studies to test if PPM elicit effort in judgment formation. 329 Study 1 aims to test PPM in a controlled setting. We recruit participants for an online experiment where they are presented with pairs of virtual boxes, containing yellow and blue 331 balls of unknown proportions. In each pair, one of the boxes is the 'actual box' with equal 332 probability. Participants are asked to pick a box within each pair. Before making a pick, 333 participants could independently draw a single ball from the actual box by completing a real 334 effort task, which involves counting the number of zeroes in a binary matrix. In this design 335 the actual box is known to the experimenter, implying that the information is verifiable. 336 Testing the PPM in a verifiable task allows us to implement incentives for ex-post accuracy 337 as a benchmark. Study 1 consists of three experimental conditions in which participants 338 complete the same task. The control condition offers fixed rewards (a flat participation fee) 339 while the two treatments implement PPM incentives and incentives for ex-post accuracy. 340 Results suggest that the PPM elicits significantly more effort than fixed rewards while the 341 effort is highest under incentives for ex-post accuracy. As discussed before, ex-post accuracy 342 is not observable in practical elicitation problems of unverifiable information. The results of Study 1 suggest that the PPM are effective when ex-post rewards are not feasible.

Study 2 explores the feasibility of PPM in a practical problem of elicitation of unverifi-345 able information. In response to the Covid-19 pandemic in 2020, governments around the world issued guidelines for social distancing and other safe practices. Policy makers would like to know if such guidance is followed by the public. When asked to self-report if they 348 were following a safe practice, people may not recall instances where they failed to do so. In 349 addition, people may be reluctant to admit unsafe practices due to the social stigma associ-350 ated with such anti-social behavior. We implement the PPM in an online survey aimed at 351 the residents of the UK. Participants are asked 8 questions, each involving an unsafe practice 352 according to the Covid-19 guidance issued by the UK government. We find that under the 353 PPM incentives, participants are more likely to admit not following the guidance and they took longer to respond on average. Study 2 allows us to test the PPM in a setup where psychological costs as well as effort costs are relevant.

357 3.2 Study 1 - PPM in a simple prediction task

358 3.2.1 Design and procedures

Tasks. Participants complete 10 prediction tasks. Each prediction task displays a pair of boxes as shown in Figure 1 below. There are 10 such pairs and each pair appears in a single prediction task only. One of the boxes in each pair is set as the 'actual box' via a virtual coin flip prior to the experiment. Participants are informed that one of the boxes is the actual box, but they do not know which. In each task, participants are asked to pick one of the boxes, which may affect their rewards depending on the experimental condition.

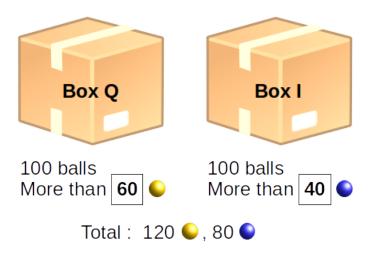

Figure 1: An example pair of boxes

In Figure 1, there are 120 yellow and 80 blue balls in total. Box Q contains more than 60 yellow balls while Box I contains more than 40 blue balls. The exact number of balls of each color are determined randomly according to the specifications. Hence, the number of yellow balls in Box Q is within (60, 100]. For example, if Box Q contains 80 yellow and 20 blue balls, Box Z contains 40 yellow and 60 blue balls. In the experiment, pairs of boxes are

presented as shown in Figure 1. Thus, participants do not know the exact number of yellow and blue balls in a box. The boxes are constructed such that the left box (Box Q in Figure 1) always contains more than half of the total number of yellow balls. Table A1 in Appendix A provides the composition of all 10 pairs.

Before picking a box, each participant is offered a choice to observe a single draw from
the actual box with replacement. Participants have to complete a real effort task to observe
their draw. The effort task is counting the number of 0s in a matrix. Figure 2 shows one
such matrix. There is a unique matrix for each effort task and there is a single effort task
associated with each prediction task. The number of 0s in each matrix varies between 8 and
16.

0	0	1	1	0	1
1	0	0	1	0	0
0	0	1	1	1	1
0	0	1	1	0	1

Figure 2: An example binary matrix

The sequence of events in each prediction task is as follows: First, participants are shown 380 a pair of boxes and asked if they want to complete the effort task. Participants skipping the 381 effort task are immediately asked to pick a box. Otherwise, they are presented the associated 382 binary matrix and asked to report the number of 0s. They are required to report an accurate 383 count to proceed and are allowed an unlimited number of retries to do so. Upon reporting the accurate count, the participants observes a personal random draw, which is either a blue or a yellow ball, and proceed to picking a box. 386 **Link with the theory.** The prediction task is a representation of the binary question 387 Q, where the two boxes in any pair correspond to the possible answers. Let us assimilate 388 reporting picking the left (right) box with $r_i = 1$ ($r_i = 0$). The effort task corresponds to 389 the costly signal c_i in the theoretical framework. Participants are allowed to skip the effort 390

task, in which case they make a pick without observing a draw. We can denote $s_i = 1$ the fact of drawing a yellow ball. In any given pair, the total number of yellow (and blue) 392 balls are known and boxes are a priori equally likely to be the actual box, which induces a 393 common prior expectation on the number of yellow balls in the actual box. For example, 394 the common prior expectation of getting a yellow ball (i.e. getting signal 1) in Figure 1 395 is $\bar{\omega} = 0.6$. Participants drawing a yellow (blue) ball increase their probability of the left 396 (right) box being the actual box. Hence, signals unequivocally influence belief and revealing 397 signals coincides with $r_i = s_i$. The representations of v and p are explained in the rewards 398 below. 399

Design & Rewards. We set up three experimental conditions which differ only in reward 400 structure. In the Flat condition, participants receive a fixed reward of £3.25 for completing 401 the experiment. In the Accuracy treatment, participants receive a basis reward of £3.25. 402 In addition, they earn £0.20 per accurate pick and lose £0.20 per inaccurate pick, where 403 the accurate pick in a pair is picking the actual box. Thus, a participant's total reward 404 is within [£1.25, £5.25]. The *PPM* treatment implements our new incentive mechanism. 405 Similar to the accuracy treatment the basis reward is £3.25. In addition, participants may earn a bonus from each pick which is determined by their peers' picks in the same pair and composition of the boxes. To illustrate, consider a participant who is asked to pick a box in 408 the pair shown in Figure 1. Suppose, among all other participants, 82% picked Box Q and 409 18% picked Box I. Then, the participant earns $82-60=22\mathrm{p}$ when picking Box Q, loses 410 40-18=22p if Box I. The value of the asset v for a given box is simply the percentage of 411 people who pick that box. The number within the square below each box corresponds to the 412 price p. We set $\pi = 1$, so the bonus per task is simply v - p. A negative total reward in the 413 PPM condition is possible but extremely unlikely. Table B1 in Appendix B shows that the 414 minimum realized reward was £2.05. Appendix B further describes how expected bonuses 415 were kept comparable between the Accuracy and the PPM treatments. 416

Participants in the Flat condition have no direct financial incentives to complete the

417

effort tasks as their reward does not depend on prediction accuracy. In contrast, rewards in the accuracy condition are determined by prediction accuracy. Thus, participants in the 419 accuracy condition could be expected to complete effort tasks more frequently to maximize 420 their accuracy. The PPM condition also provides incentives to complete effort tasks if, 421 as predicted by the theory, participants consider their signal informative on others' picks. 422 Consider a truthful equilibrium outcome for the example in Figure 1. If the actual box is Q, 423 then more than 60% of others to draw a yellow ball and pick Q. The percentage of blue draws 424 (and I picks) will be less than 40%. In that case, picking Box Q gives a positive expected 425 payoff while picking Box I leads to a loss. The opposite is true when Box I is the actual 426 box. Participants have an incentive to complete the effort task because their draw provides 427 information on the actual box, which in turn suggests which box is more likely to be picked 428 more often than the prior (60 and 40 for Boxes Q and I in Figure 1). 429

Note that the exact expected payoff of a participant depends on her beliefs on the com-430 position of the boxes, which are not restricted by the experiment following the heterogeneity 431 of posterior expectations in the theory. Suppose the participant have a uniform belief over 432 all possible compositions of Boxes Q and I given that Box Q contains more than 60 yellow 433 and Box I contains more than 40 blue. In that case, the participant expects 80 yellow in Box Q and 60 blue in Box I, implying that 80% (60%) are expected to pick Box Q (I) if the actual 435 box is Box Q (I). Since the priors 60 and 40 respectively, the participants expect 20p from 436 picking the actual box and -20p from a wrong pick. In the absence of a draw, Q and I are 437 equally likely to be the actual box and the expected payoff is zero. If a participant completes 438 the effort task and draws yellow, the expected payoff from picking Box Q is Pr(actual box 439 is Q | yellow) 20 + Pr(actual box is I | yellow)(-20). Observe that, in this example, the 440 expected payoff conditional on the draw is identical in the Accuracy and PPM conditions 441 because win/loss per task in the Accuracy condition is also 20p. This need not hold for all 442 participants and tasks. The expected payoff in the PPM condition depend on the partic-443 ipants beliefs on the composition of the boxes. So, the expected bonus from an accurate

from an accurate pick in each prediction task. Consider uniform beliefs over the possible yellow/blue ratios, given participants' information on the pairs. Then, the expected bonus from a truthful pick ranges between 15p and 25p across the tasks, with an average of 20p. In order to make the PPM and Accuracy conditions payoff-equivalent, we set the bonus per 449 pick in the Accuracy condition at 20p. 450 Participants. We recruit 210 participants from Prolific, an online platform for conducting 451 surveys. We restrict our participant pool to U.S. citizens who are students at the time of 452 the experiment. Table B1 in Appendix B provides further information on the participants. 453 **Procedure.** The experiment was published on Prolific in May 2020 and implemented via 454 Qualtrics. Participants are randomly selected into one of the experimental conditions. They 455 are first presented with instructions, which differ across the experimental conditions in re-456 wards only. Then, the participants respond to a quiz question about the rewards in their 457 experimental conditions. Depending on the answer, the experiment provides feedback with 458 an example illustration of the rewards. The quiz marks the end of instructions and the be-459 ginning of the main body of the experiment. Participants complete the 10 prediction tasks. 460 The order of the prediction tasks is randomized. Finally, participants complete a short survey on demographics and their experience in the experiment. Appendix A.1 provides the full text of the instructions, the quiz stage and the final survey.

pick may differ from 20p. Table A2 in Appendix A.1 shows the range of anticipated bonus

$_{464}$ 3.2.2 Results

The primary question of interest is whether participants are more likely to seek costly information under the incentives provided by a PPM compared to fixed rewards. The effort task completion in control and PPM treatments allows us to test the effect of PPM incentives in eliciting effort. Furthermore in our prediction task, the ground truth (the actual box in any pair) is known to the experimenter. The accuracy treatment implements rewards for ex-post accuracy, which are not feasible in practice for elicitation without verification. We

compare accuracy and PPM treatments to assess the effectiveness of PPM incentives relative to ex-post rewards.

We measure the frequency with which participants completed the effort tasks across the experimental conditions. Figure 3 depicts the percentage of instances per prediction task and experimental condition where participants completed the associated effort task.

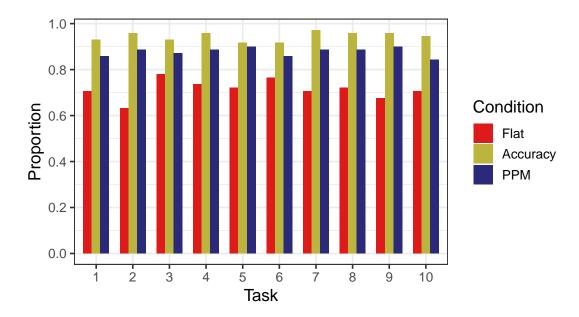

Figure 3: Proportion of times participants completed the effort task associated with the prediction task on the x-axis.

The effort level is substantial, even in the Flat condition. Effort task completion is higher 476 in the PPM and accuracy treatments while the latter achieves the highest proportions. Figure 477 3 suggests that incentives provided by a PPM is effective in eliciting a higher proportion of 478 informed judgments compared to a fixed reward. Incentives in the accuracy treatment are the most effective in eliciting effort. Figure 3 also indicates that the effort level in the PPM condition is similar across tasks. Section 3.2.1 discussed that the expected bonus from an 481 accurate pick may differ according the composition of the boxes, which vary across tasks. 482 Figure C1 in Appendix C shows that the effort rate does not differ significantly across the 483 levels of expected bonuses provided in Table A2. 484

For a statistical analysis on effort task completion, we estimate logistic regressions where

485

Table 1: Marginal effects, logistic regression (baseline category: Flat)

probability of effort task completion is the dependent variable. Table 1 below shows the 486 average marginal effects. The pooled data includes 2100 decisions to complete the effort task 487 or not. We include binary indicators for the experimental conditions as dependent variables. 488 The coefficient of 'PPM' in Table 1 measures the average marginal effect of implementing 489 PPM incentives (instead of a flat fee) on the likelihood of effort task completion. The coefficient of 'Accuracy' measures the same for rewarding participants for ex-post accuracy. Models (1) and (2) use the whole sample of participants. In (3) and (4), participants who 492 gave an incorrect answer in the post-experimental quiz are excluded to construct a filtered 493 sample. Specifications (2) and (4) also include various controls. The variables 'US citizen' 494 and 'Female' are binary indicators for US residents and gender respectively while 'Age' is a 495 numeric variable. In all models, standard errors are clustered at participant level. 496 In all specifications, the marginal effects for PPM and accuracy treatments are positively 497

significant. Based on model (2), we see that a participant in the PPM treatment is 14

498

percentage points (ppt) more likely to complete the associated effort task in a given prediction task. Incentives provided by a PPM motivates agents to exert more effort compared to a fixed payment. For a comparison between Accuracy and PPM, Table C2 estimates the same logistic regression except that PPM is the baseline category. Incentives for ex-post accuracy is 7-9 ppt more likely to elicit effort compared to a PPM. We can infer that incentives for expost accuracy is the most effective in effort elicitation, followed by PPM and flat payments. In the absence of verifiability, PPM provides an alternative for incentivizing effort.

We now investigate if participants revealed their signals, which means picking the left 506 (right) box when a yellow (blue) ball is drawn. Given the simplicity of the predictions 507 task, participants do not have any external motives to make a hide their signals. However, 508 deviations from signal revelation may occur due to confusion or errors, or due to beliefs that 500 others will deviate. Figure 4 shows participants' picks given their draw. The 3x3 grid depicts 510 the three experimental conditions as well as the three possible situation after the effort task. 511 Participants receive a yellow or blue draw if they complete the effort task. Alternatively, 512 they do not receive a draw if they skip the effort task. The bars show the number of picks 513 in each task. Since picking the left (right) box when the draw is yellow (blue) is the signal-514 revelation strategy, the number of left (right) picks are represented by yellow (blue) colored bars. The black dots show participants' prior expectation on the number of yellow balls in the actual box, given that left and right boxes are equally likely to be the actual box. Table A2 in Appendix A provides the prior expectations on the number of yellow balls in each 518 task. 519

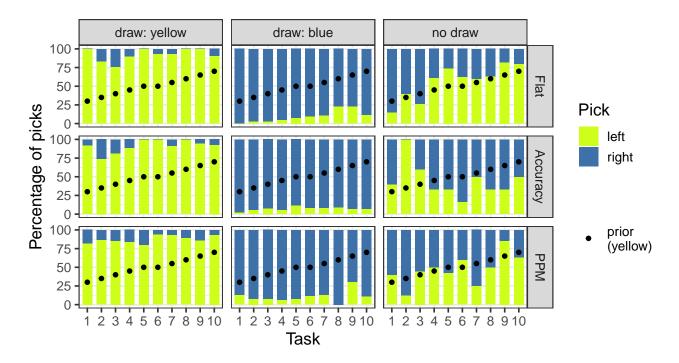

Figure 4: Participants' picks

Figure 4 strongly suggests that the participants mostly reveal their signals. Participants 520 who observe a yellow (blue) draw typically pick the left (right) box. The distribution of picks 521 in PPM and Accuracy are very similar, so we can argue that the PPM incentives reveals 522 acquired signals as well as Accuracy incentives do. The same is true for the Flat condition. 523 The right-hand panel of Figure 4 illustrates the strategy participants use if they do not 524 draw a ball. Interestingly, participants in the PPM treatment (and in the Flat treatment) 525 appear to follow a mixed strategy (at the aggregate level), reporting left with a probability 526 equal to the prior, as described in the equilibrium of Proposition 3. The proportion of left 527 reports and the prior are correlated (Pearson: $\rho = 0.64$, p = 0.048) and not significantly 528 different (t-test t = -0.34 p = 0.739) for PPM participants who do not draw a ball, whereas 529 they are uncorrelated and significantly different for those who draw a yellow ball or a blue ball (see Table C1 in Appendix C).

532 3.3 Study 2 - Eliciting Covid-19 experiences using PPM

Study 2 implements PPM incentives in measuring if the residents of the UK followed 533 safety guidance during the Covid-19 pandemic. For most of the safe practices in the guidance, 534 it is not feasible to monitor all individual behavior. Self-reported behavior is practically 535 unverifiable. In an unincentivized or a flat-fee survey, participants may not exert the mental 536 effort to recall (signal acquisition) and report their behavior truthfully (signal revelation). 537 Furthermore, reporting costs can be asymmetric. Unsafe behavior is typically stigmatized 538 and likely to be under-reported (Tourangeau and Yan, 2007). We investigate if the PPM 530 motivate participants to spend more time in answering questions and report their unsafe 540 practices at a higher rate. 541

$_{542}$ 3.3.1 Design and procedures

Tasks. Participants, all from the UK, are presented a survey consisting of 8 statements. Each statement describes a situation that was considered unsafe and inadvisable (if not prohibited) by the UK Covid-19 guidance at the time of this survey. All situations involve others' actions, thereby mitigating one's own responsibility and lowering the stigma (in the terms of our model, to keep cost a_i reasonably low). For each statement, participants pick 'true' or 'false' to self-report if they have been in the described situation. Table 2 provides the list of questions:

	Statement
1.	I have been in an elevator with another person in it at least once in the last 7
	days
2.	I may have stood less than 2 metres away from the person in front in a queue
	at least once in the last 7 days
3.	I was seated less than 2 metres away from someone who is not part of my
	household in a restaurant/cafe/bar at least once in the last 7 days
4.	I have been in a social gathering with more than 6 people who are not part of
	my household at least once in the last 7 days
5.	I have been in a busy shop/market with no restrictions on number of customers
	at least once in the last 7 days
6.	I participated in an indoor activity with more than 6 people who are not part
	of my household at least once in the last 7 days
7.	I have been in a shop/market where one or more of the staff did not wear a
	mask at least once in the last 7 days
8.	I had an interaction with someone experiencing high body temperature, per-
	sistent cough or loss of taste/smell at least once in the last 7 days

Table 2: Covid-19 survey questions

We ran this survey for two weeks with a new sample of participants every week. The two 550 iterations of the survey are referred to as week 1 and week 2 surveys respectively. As we will 551 introduce below, week 1 and week 2 surveys include experimental conditions that implement 552 the PPM. We also run a week 0 survey to elicit information necessary to initialize the PPM. 553 The week 0 survey uses the same questions, but they are presented in a slightly different way 554 to elicit more information on the number of instances participants engaged in the described 555 behavior. For example, question 1 in Table 2 is presented as 'In the last 7 days, I have been 556 in an elevator with another person in it ...' and the participant picks one of the following 557 answers: 'once or more', 'twice or more', '3 times or more', '4 times or more', '5 times or 558 more'. Based on the results of the week 0 survey, we decided to implement two versions of 559 each survey in weeks 1 and 2. Both versions ask the questions in Table 2, but in the second 560

version 'at least once' is replaced with 'at least twice' in each question. We provide more information on how week 0 survey is used in the design below.

Design. In week 0 survey, participants receive a flat fee only. In week 1 and 2 surveys, we manipulate incentives to create control and treatment conditions. As ground truth (guideline compliance) is not observable, an accuracy treatment as in study 1 is unfeasible. In the control, participants are rewarded with a flat fee for completing the survey while the treatment implements the PPM incentives. Figure 5 shows the experiment interface in the PPM condition.

Question 2 of 8 (show instructions)

Please try to remember how many times you were in the following situation:

I was seated less than 2 metres away from someone who is not part of my household in a restaurant/cafe/bar at least once in the last 7 days.

Figure 5: A screenshot from the treatment condition

The interface displays the statement and requires participants to pick 'true' or 'false'.

The text below each alternative indicates the percentage of participants who endorsed that
alternative in the previous week's survey. Recall that in our Bayesian setup, agents have
a common prior expectation $\bar{\omega}$. To implement Assumption 2 in practice, we provide the
participants with the latest realization of ω . The center sets $p = \bar{\omega}$, which leads to a
separating equilibrium. Furthermore, participants' bonus depends on the endorsement rates.

In Figure 5, the endorsement rate of 'true' in the last iteration is 44%. A participant

who picks 'true' in this iteration wins a positive (negative) bonus from this question if the realized endorsement rate in this iteration exceeds (falls below) 44%. The same holds for 577 'false', except that the threshold is 56%. Thus, the PPM condition essentially implements a 578 repeated PPM where last iteration's realization determines the price for the current iteration. 579 We provide more information on the rewards below. The PPM incentives are expected to 580 incentivize mental effort and/or overcome the psychological costs of reporting one's actual 581 behavior. If PPM incentivizes signal acquisition, we may expect decision times—a proxy 582 for mental effort—to be longer. If PPM incentivizes signal revelation in the presence of 583 asymmetric costs $a_i > 0$, we may expect endorsement rates for 'true' to be higher. 584

The control surveys are similar to the treatment surveys except that participants are 585 rewarded with a flat fee. We implement two different types of control surveys. In the Flat 586 condition, the survey interface does not present any information on previous iterations' en-587 dorsement rates. The Flat condition mimics how such questions would be implemented in a 588 regular survey. The Flat-PastRate survey shows the same screen as the PPM condition by displaying previous week's endorsement rates, as in Figure 5. The rewards are fixed in both 590 Flat and Flat-PastRate surveys, thus the previous endorsement rates are irrelevant. Never-591 theless, we included Flat-PastRate condition to check if merely presenting that information affects participants decision time and reports. First, processing additional information (previous endorsement rates) could, per se, increase decision times even if there is no additional 594 effort to acquire signals. Secondly, it could influence endorsement rates by social proof 595 (Cialdini, 1988) or conformity desire (Morgan and Laland, 2012). 596

Week 0 survey is used to determine the previous endorsement rates presented in the Flat-PastRate and PPM surveys of week 1. Furthermore, the week 0 survey motivates our choice to run two versions where the statements include 'at least once' and 'at least twice' respectively. Table B2 in Appendix B provides the percentage of participants who pick 'true' in each question in the week 0 survey. For '3 times or more' and higher thresholds, the percentage of 'true' picks are close to 0. Then, participants in week 1 iteration of an 'at

least 3 times' version may report 'true' simply because the threshold is very low and a few 'true' picks could easily bring the week 1 endorsement rates above the threshold. To avoid such cases, we only run two versions with 'at least once' and 'at least twice' respectively. In each week $i \in \{1, 2\}$, we implement 6 surveys in a 3 (Flat, Flat-PastRate, PPM) \times 2 ('at least once', 'at least twice') design.

Participants. As in Study 1, participants are recruited from Prolific but this time, we 608 restrict our participant pool to students who currently reside in the UK. We chose the UK 609 because it had uniform national social-distancing guidelines and sufficient Prolific partici-610 pants at the time of the study. We restricted the study to students because we needed a 611 homogeneous group such that Assumption 1 (signal technology) may plausibly hold. In total 612 692 participants completed our survey, 50 of which participated in week 0 survey while the 613 remaining 642 participated in either week 1 or 2 (but not both). Participants in a given week 614 $i \in \{1, 2\}$ are assigned randomly in one of the 6 conditions explained above. One participant 615 is excluded for being in a non-student status at the time of data collection. All surveys are 616 implemented via Qualtrics. Table B3 in Appendix B provides further information on the 617 participants. 618

Rewards. The Flat and Flat-PastRate surveys pay a fixed reward of £1.75. In the PPM surveys, participants earn £0.75 for participation. In addition, they start with an endowment 620 of £1, which represents the initial level of bonus. In each question, the bonus changes 621 according to the difference between the endorsement rate in the current survey versus the 622 endorsement rate in the previous iteration. To illustrate, suppose a participant picked 'true' 623 in a question in week 2 survey and endorsement rate of 'true' was 50% in week 1. If the 624 realized endorsement rate of 'true' in week 2 at the same question is 70%, the participant 625 wins 70 - 50 = 20p. In contrast, if the endorsement rate in week is 30%, the participant 626 loses 50 - 30 = 20p. The previous week's endorsement rate serves as the price p in a PPM 627 while the current week's endorsement rate, unknown to the participant at the decision time, 628 is analogous to realized value of the asset v. Similar to Study 1, we set $\pi = 1$ and the bonus 629

is simply v-p. For each participant in the PPM condition, we sum the gains and losses over all question to determine the net bonus. As in Study 1, the total reward can be negative in 631 the PPM condition. However, this is extremely unlikely and Table B3 in Appendix B shows 632 that the minimum reward was £1.18. 633 **Procedure.** The experiment is conducted over three weeks and consists of week 0, 1 and 2 634 surveys that take place 7 days apart. The week 0 iteration is a single survey while in weeks 1 635 and 2, participants are randomly assigned to the different conditions. In each survey of each 636 iteration, participants are first presented with instructions. Then they are asked to respond 637 to the questions, which are presented in randomized order. Finally, participants complete 638 a short survey on demographics and their experience in the experiment. Appendix A.2 639 provides the full text of the instructions and the final survey. 640 **Link with the theory.** Let us assimilate endorsing "true" for a statement with $r_i = 1$. 641 Remembering whether the situation described in the statement occurred corresponds to 642 signal acquisition cost c_i in the theoretical framework. This cost may be purely cognitive (recollection effort) but also due to the discomfort to think about it. Clicking on an answer 644 without thinking allows respondents to avoid the discomfort. The stigma to answer "true"

649 3.3.2 Results

648 $\bar{\omega}$.

Figure 6 shows the percentage of 'true' picks for each condition and version in the week
1 and week 2 surveys. Responses are pooled across questions and participants. Twelve
observations have response time longer than 60 seconds, which suggests outliers as showed
by Figure C3 in Appendix C. Table C4 provides the outliers. The "filtered" sample results
in the statistical analyses below exclude the outlier responses.

corresponds to a_i and giving an answer whilst remembering the opposite corresponds to d_i .

The previous-week endorsement rate of "true" mentioned beneath the choice corresponds to

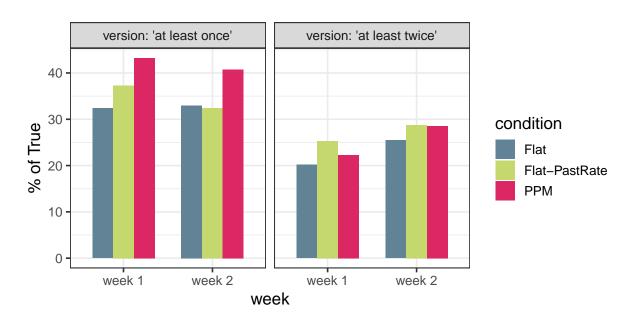

Figure 6: Percentage of 'true' picks in week 1 and 2 surveys.

In the 'at least once' surveys, the PPM survey elicits a higher percentage of 'true' re-655 sponses compared to both controls. No such difference is observed in any iteration in the 656 'at least twice' version. Figure C2 in Appendix C shows a breakdown of percentage of 'true' 657 across different questions. PPM elicits more 'true' in most questions in the 'at least once' 658 version. Recall that week 1 surveys are initialized with the unincentivized week 0 survey 659 (of a slightly different format) while week 2 surveys use data from week 1 survey of the 660 corresponding condition. Since the prior has an effect on PPM, we will analyze the response 661 data from weeks 1 and 2 separately. 662

Figure 7 depicts the response times for each version and week. We also categorize data according to the response type to see if response times differ.

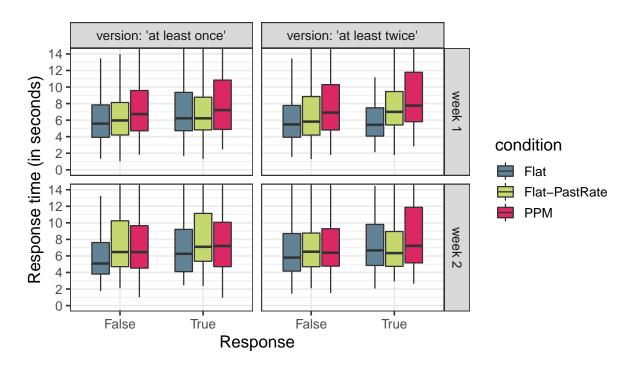

Figure 7: Response time of participants. The data points above 14 are included in calculations but not shown on the figure.

Figure 7 suggests that the median response time in the PPM condition is higher than 665 the Flat surveys in all iterations. The same is true for the Flat-PastRate surveys in week 1. However, response times in the Flat-PastRate and PPM conditions are comparable in week 667 2 surveys. To test for significance, we estimate two classes of regression models. Firstly, we estimate a logistic regression for participants' likelihood of picking 'true' in any given 669 question. Secondly, we estimate a linear regression model where response time is the de-670 pendent variable. In both models, Flat is the baseline category and binary indicators for 671 Flat-PastRate and PPM are variables of interest. We also include various demographic con-672 trols representing the age, gender and citizenship of participants. We focus here on the 673 'at least once' versions of all iterations as Figure 6 suggested a possible difference for these 674 versions only. Section C.2.2 in Appendix C performs the same analysis for 'at least twice' 675 survey. 676

Table 3 presents the average marginal effects from the logistic regressions. Models (1,2) and (4,5) show the results with outliers excluded, while (3) and (6) include all responses.

Table C5 in Appendix C provides the corresponding parameter estimates. In all models, standard errors are clustered at the participant level.

Table 3: Logistic regression, average marginal effects

The average marginal effects in Table 3 show that the PPM survey elicits a higher frequency of 'true' picks. According to model (1), a participant in the PPM condition of week 1 survey is 9 ppt more likely to report 'true' for a given statement compared to a participant in the Flat condition. In contrast, Flat-PastRate condition has no effect. A similar result holds for the week 2 survey where the marginal effect of the PPM condition is estimated to be 8 ppt. Results support the equilibrium characterized in Proposition 4. PPMs motivate participants to declare unsafe practices at a higher rate, which suggest that such practices are under-reported in basic surveys. There are two possible mechanisms. PPM incentives

may dominate potential reporting costs associated with the stigmatized response and/or they encourage participants to exert more mental effort. The next paragraph analyzes response time, as a proxy for mental effort.

Table 4 presents the OLS estimates where the dependent variable is the response time in seconds. Similar to Table 3, standard errors are clustered at the participant level.

^{***} p < 0.001; ** p < 0.01; * p < 0.05; + p < 0.1

Table 4: Response time regressions.

The response time regressions show mixed results. In models (1)-(3), participants in the PPM survey spend significantly more time in their responses than the Flat survey. However,

the week 2 results suggest otherwise. Models (4)-(6) do not indicate a strong difference in response times between the PPM and Flat surveys. The test of the two parameters (PPM vs 697 Flat-PastRate) in (2) results in a significant difference (mean difference = 1.846, t = 2.348, 698 p = 0.019) while the same test in (5) suggests no difference (mean difference = -0.6248, 699 t = -0.924, p = 0.356). Thus, a difference in response times relative to the Flat survey 700 could also be the result of the presentation of more information in both Flat-PastRate and 701 PPM surveys. Week 1 results also suggest that response times are higher for those answering 702 "True", which could indicate that respondents exerted more mental effort to remember their 703 week. The effect does not vary with the treatments. Week 2 results show no effect for the 704 response type. 705

To sum up, the PPM treatment increased the probability to report deviations from
Covid guidelines, but this effect does not necessarily arise from additional mental effort as
approximated by response time. We can exclude that the effect is an artefact of mentioning
the answer rates of the previous week, creating some social norms, since treatment FlatPastRate did not differ from treatment Flat. Hence, higher rates of admitting an unsafe
practice indicate that the PPM incentives dominate potential reporting costs associated
with the stigmatized response.

713 4 Discussion

$_{^{14}}$ 4.1 Theoretical limitations

The signal technology assumption includes anonymity, i.e, that the probability to obtain signal 1 is the same for all agents. This assumption, even though common in the theoretical literature, limits possible applications. It can be easily implemented in artificial studies but for relevant topics, it requires implementing PPMs on homogeneous groups of respondents.

PPM, like similar mechanisms, assume risk neutrality. Risk aversion could decrease the perceived incentives provided by the mechanism. When participation is compulsory however,

the no effort strategy is also risky. In the presence of high risk aversion, a degenerate equilibrium with no-one providing effort and everyone reporting the same answer would dominate equilibria with efforts. Loss aversion could also distort the results as some but it is unlikely to be substantial for the type of amounts used in surveys and in the presence of an initial endowment as in our studies. So far, the only mechanism to elicit unverifiable signals explicitly handling risk attitudes and even non-expected utility has been proposed by Baillon and Xu (2021). It requires, however, multiple questions with the exact same signal technology.

As illustrated by Propositions 1 to 3, there are several types of equilibria. To those should
be added equilibria in which signal 1 agents report 0 and conversely. These latter equilibria
did not occur in Study 1. Interestingly, at the aggregate level, participants seemed to play
the strategies of Proposition 3, and those who did not draw a signal played a mixed strategy
(at the aggregate level) where the randomization probability was equal to the prior.

We considered a very simple model, binary in all dimensions. Effort could be continuous, signal informativeness could be a function of effort, and answers could be non-binary. We leave these refinements for future research. Similarly, we limited our analysis to some types of psychological costs. Others would be possible but are unlikely to substantially change the results. For instance, symmetric reporting costs would not bring new insights but only require higher payoffs (by rescaling π).

The asymmetric reporting cost, a_i , is exogenous. However, setting up PPMs (or any incentive mechanism) may necessitate to break anonymity to process payment. The lack of anonymity may then increase a_i further. There are practical solutions to this problem. For instance, as we did in Study 2, one can erect a 'China wall' between the payment provider (Prolific, who knows identity but not people's answer) and the center (the researchers who know the answers but not the respondents' identities).

4.2 Empirical limitations

Study 1 borrowed tasks from the experimental literature, which allowed us to observe effort and signal acquisition. The main drawback is that those tasks were artificial, and may have been seen as quite unnatural. Furthermore, there was hardly any reason not to reveal the acquired signal. Study 2 was conducted to test whether PPM elicits signal acquisition and revelation in a more realistic context. Results of Study 2 give credence to the real-world validity of PPM but signal acquisition can only be proxied by decision time and ground truth is not observable.

Both studies were conducted online with participants from the Prolific platform. Partici-754 pants from online platforms take part in experiments in an uncontrolled setting, for example, 755 from home. This lack of experimental control has elicited concerns amongst researchers. 756 However, experimental research has shown that this concerns is largely unfounded. Hauser 757 and Schwarz (2016) demonstrated that participants from an online platform are more at-758 tentive than college students. Eyal et al. (2021) demonstrated that Prolific outperformed 759 other participant platforms regarding data quality. To ensure high data quality in the cur-760 rent research, post-experimental quiz questions were included in Study 1, allowing to remove 761 inattentive participants. In Study 2, the instructions in the PPM condition emphasize that 762 the bonuses depend on others' responses. 763

We initially planned to run Study 2 over four weeks, but we had to stop earlier when the pandemics amplified in the UK (second wave), making our questions less applicable. Fortunately, data collected during weeks 0, 1, and 2 already provide valuable insights on the effectiveness of PPM in a real-world context with unverifiable ground truths.

In study 2, participants were asked about their violations of COVID guidelines. The discrepancy between the prevalence of self-reported lies (Debey et al., 2015) and lies told during experimental research (Feldman et al., 2002) demonstrates that people are reluctant to admit anti-social behavior. Since violations of COVID guidelines could negatively affect the health of both oneself and others, a violation of COVID guidelines can be seen as immoral

behavior. However, the questions we use limited this effect. In most statements, noncompliance could have been due to behavior of others. Results of Study 2 demonstrate that
participants in the PPM condition admitted more violations of COVID guidelines than in
both control conditions. PPM may have helped overcome the discomfort of reporting noncompliance with health guidelines (a_i in the theory). However, PPM has no effect though
when we replace 'at least once' by 'at least twice' in the statements. In the latter case, it is
more difficult to minimize one's responsibility and the asymmetric cost is therefore likely to
be higher.

5 Conclusion

When answers to questions are unverifiable, researchers and practitioners typically resort to simple surveys with fixed rewards, which do not provide incentives to acquire costly information and reveal it. Since Crémer and McLean (1988), the economic literature has proposed many mechanisms to elicit private signals but their practical use has been limited, due to their complexity. This paper introduces PPM, a simple market mechanism that incentivize agents to acquire and reveal private signals for binary questions. A first study demonstrates that it stimulates costly effort to acquire information and a second study shows that it can be implemented in practice to elicit more truthful answers to mildly stigmatizing questions.

Table A1: The content of boxes and subjects' information in each pair

Table A2 shows the theoretical prior and posterior beliefs of a subject in each pair.

Consider pair 1 where there are 60 yellow and 140 blue balls in total. The left (right) box includes more (less) than 30 yellow. Prior to observing the draw, each box is equally likely to be the actual box. Thus, the common prior expectation on yellow (blue) is 30 (70). If the draw is yellow, the left box will be considered more likely. Then, the posterior expectation on yellow will be within (30, 60], while the posterior on blue is simply 100 minus the posterior on yellow. Note that the exact posterior expectation of a subject depends on the prior belief on the composition of the boxes, which is not restricted by the experiment, in accordance

with the theoretical framework. Subjects with a yellow (blue) draw expect left (right) box to be more likely for the actual box. Under the equilibrium in Proposition 2, subjects with 900 a yellow (blue) draw would pick the left (right) box. The last column in Table A2 gives the 901 range of expected bonus in the PPM condition if the subject's pick (left if yellow draw, right 902 if blue draw) corresponds to the actual box. Note that E[bonus | pick = actual] = 20p for all 903 pairs in the Accuracy condition. This constant value is set to achieve a payoff equivalence 904 between the PPM and Accuracy conditions. To illustrate, consider pair 1 and suppose a 905 subject with a yellow draw has a uniform belief over all possible Yellow/Blue compositions 906 in the left box. Then, the exact E[bonus | pick = actual] is 15p. Under the uniformity 907 assumption, the expected bonus ranges from 15p to 25p across all pairs, with an average of 908 20p. 909

	Pri	ors	Posterior on Yellow		Range of E[bonus pick = actual]	
Pair	Yellow	Blue	Yellow draw	Blue draw	Posterior (draw) - Prior (draw)	
1.	30	70	(30,60]	[0,30)	(0p,30p]	
2.	35	65	(35,70]	[0,35)	(0p,35p]	
3.	40	60	(40,80]	[0,40)	(0p,40p]	
4.	45	55	(45,90]	[0,45)	(0p,45p]	
5.	50	50	(50,100]	[0,50)	(0p,50p]	
6.	50	50	(50,100]	[0,50)	(0p,50p]	
7.	55	45	(55,100]	[0,55)	(0p,45p]	
8.	60	40	(60,100]	[0,60)	(0p,40p]	
9.	65	35	(65,100]	[0,65)	(0p,35p]	
10.	70	30	(70,100]	[0,70)	(0p,30p]	

Table A2: Priors, posteriors and expected bonus conditional on an accurate pick.

Complete instructions for each experimental condition, the quiz question and the final survey on demographics are included below.

Instructions - PPM condition

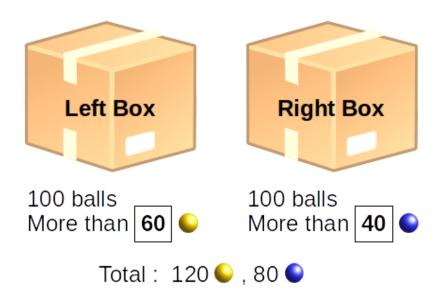

912Instructions

(page 1 out of 5)

In this experiment, you will answer 10 questions in total.

In each question, there are two new boxes, which contain yellow (\bigcirc) and blue (\bigcirc) balls in different proportions.

A picture like the one below will give you information on the boxes:

Numbers may change in each question. But, following is always true:

- ...Left box always contains more than half of all 🌑
- ...Right box always contains more than half of all 🔵
- ...Both boxes always contain 100 balls each.

In the example above, if left box contains 68 \bigcirc and 32 \bigcirc , right box contains 52 \bigcirc and 48 \bigcirc

Instructions

(page 2 out of 5)

In each question, one of the boxes is the 'actual box'.

The actual box is predetermined by an unbiased coin flip. It is same for all participants, including you.

913

A ball will be drawn randomly from the actual box for you. Following is an example draw:

Note that...

- ...if you draw •, Left box is more likely.
- ...if you draw •, Right box is more likely.

The color of your draw helps you guess the actual box.

Instructions

(page 3 out of 5)

To see the color of your draw, you need to complete an **effort task**.

You will first see the following question:

Would you like to work on the effort task?

If you select 'Yes', you will be presented a table as below:

0	0	0	1	0	0
0	0	0	0	1	1
1	0	0	1	1	0
1	0	1	0	1	0

Your task is to count the number of 0s.

There is no time limit. You can try multiple times.

Once you submit the correct answer, you observe your draw.

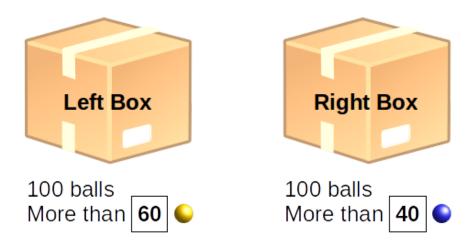

You may skip the effort task by selecting 'No'. Then, you will not see the color of your draw.

Instructions

(page 4 out of 5)

Finally, you will pick one of the boxes. The question will appear as below:

Which box do you pick?

You may click on...

Left box if you pick Left box Right box if you pick Right box

Your pick will be submitted when you click

Submit

Which box do you pick?

You may tap...

Left box if you pick Left box Right box if you pick Right box

Your pick will be submitted when you tap

Submit

Instructions

(page 5 out of 5)

You will earn £2 bonus, on top of £1.25, for completing the experiment.

In addition, you may earn bonus from each question.

Let's see how it works with the example boxes:

Total: 120 🔵 , 80 🔮

There will be at least 50 other participants in the experiment.

After the experiment, we calculate the percentage of participants other than you who pick each box.
We compare those percentages to the numbers in
Suppose 79% picked Left, 21% picked Right. Then,you win 79 - 60 = 19p if you picked Leftyou lose 40 - 21 = 19p if you picked Right
So, you win money if you pick the box that others will pick more often than indicated in .
The color of your draw helps you guess others' draws, which may affect their picks.
The maximum total gain from your picks is +£2 and the maximum total loss is -£2.
So, your total reward at the end of the experiment is between £1.25 and £5.25.

Instructions

(page 5 out of 5)

You earn £2 bonus, on top of £1.25, for completing the experiment.

In addition, you earn a bonus from each question if you guess the actual box accurately.

Let's see how it works with the example boxes:

Suppose instead Right is the actual box. Then,...

...you lose 20p if you picked Left.

...you win 20p if you picked Right.

The maximum total gain from your picks is +£2 and the maximum total loss is -£2.

So, your total reward at the end of the experiment is between £1.25 and £5.25.

Powered by Qualtrics

Quiz

Here's a small quiz on rewards!

Which of the three statements is most accurate?

My bonus is fixed, regardless of the box I pick.

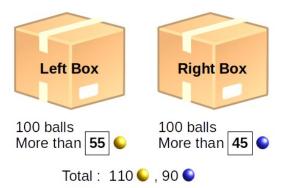

My bonus depends on the actual box and the box I pick.

My bonus depends on the box I pick and what other participants pick.

Participants receive feedback according to their answer. In the PPM condition, the correct answer is "My bonus depends on the box I pick and what other participants." If the correct answer is reported, the following is displayed:

TRUE! Your bonus depends on the box you picked and what other participants picked.

Here's an example. Suppose you have the following pair of boxes:

Suppose, of all other participants, 65% picked Right, 35% picked Left

Let's say your draw was
and you picked Right.

Then, you win **65**-45 = 20p.

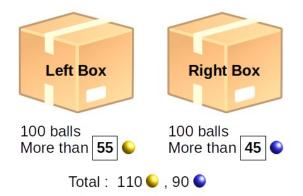

If you had picked Left instead, you would have lost 55-35 = 20p.

So, your reward depends on your pick AND other participants' picks.

The color of your draw helps you guess others' draws, which may affect their picks.

FALSE! Your bonus depends on the box you picked and what other participants picked.

Here's an example. Suppose you have the following pair of boxes:

Suppose, of all other participants, 65% picked Right, 35% picked Left

Let's say your draw was
and you picked Right.

Then, you win 65-45 = 20p.

If you had picked Left instead, you would have lost 55-35 = 20p.

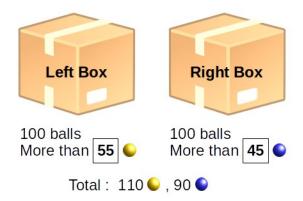

So, your reward depends on your pick AND other participants' picks.

The color of your draw helps you guess others' draws, which may affect their picks.

In the Flat condition, the correct answer is "My bonus is fixed, regardless of the box I pick." If the correct answer is reported, the following is displayed:

TRUE! Your bonus is fixed, regardless of the box you pick.

Here's an example. Suppose you have the following pair of boxes:

It does not matter if your pick is the actual box or not.

Other participants' picks are also irrelevant.

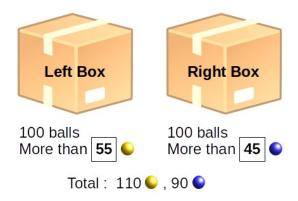

You will earn £2 bonus for completing the experiment. Your total reward will be £3.25.

There is no bonus for working on the effort tasks.

If a participant picks one of the wrong answers, the following is displayed:

FALSE! Your bonus is fixed, regardless of the box you pick.

Here's an example. Suppose you have the following pair of boxes:

It does not matter if your pick is the actual box or not.

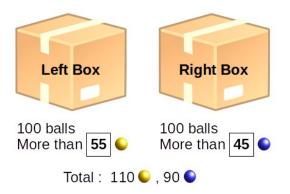

Other participants' picks are also irrelevant.

You will earn £2 bonus for completing the experiment. Your total reward will be £3.25.

There is no bonus for working on the effort tasks.

TRUE! Your bonus depends on the actual box and the box you picked.

Here's an example. Suppose you have the following pair of boxes:

Suppose Right box is the actual box.

Let's say your draw was
and you picked Right.

Then, you win 20p because you guessed the actual box accurately.

If you had picked Left instead, you would have lost 20p.

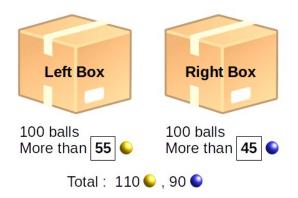

So, your reward depends on your accuracy only.

The color of your draw helps you make an accurate guess.

If a participant picks one of the wrong answers, the following is displayed:

930

Here's an example. Suppose you have the following pair of boxes:

Suppose Right box is the actual box.

Let's say your draw was
and you picked Right.

Then, you win 20p because you guessed the actual box accurately.

If you picked Left instead, you would have lost 20p.

So, your reward depends on your accuracy only.

The color of your draw helps you make an accurate guess.

Thank you for your answers!

931

To conclude, we would like you to answer some questions about your personal background and your experience in this experiment

How old are you?									
	v								
What is your gend	What is your gender?								
Male.									
Female.									
Other / Prefer no	t to disclose.								
What is your education level?									
Did you receive a t	raining in statistic	s? If yes, on which lev	vel?						
	~								
When did you receive this training?									
~									
How clear were the instructions in this experiment?									
Very clear.	Mostly clear.	Understandable, but not very clear.	Mostly unclear.	Very unclear.					

Which of the three statements is most accurate?

My bonus depends on the actual boxes and the boxes I picked.	
My bonus depends on the boxes I picked and what other participants picked.	
My bonus is fixed, regardless of the boxes I picked.

933 A.2 Study 2

Complete instructions for each experimental condition and the final survey on demographics are included below.

Instructions - PPM condition

936Instructions

(page 1 out of 5)

Welcome! In this survey, you will answer 8 questions on the COVID-19 pandemic.

The UK government issues COVID-19 guidance and passes regulations to control the pandemic.

This survey aims to collect data on people's behaviour to assess whether such guidelines are helpful.

In each question, we will ask you about your experience for certain situations related to the pandemic.

Instructions

(page 2 out of 5)

Here's an example on how questions will appear:

I may have stood less than 2 metres away from the person in front in a queue at least once in the last 7 days.

True False

You may pick True or False depending on whether you have been in the situation described in the question.

Your pick will be submitted when you click

Submit

You may pick True or False depending on whether you have been in the situation described in the question.

Your pick will be submitted when you tap

Submit

Instructions

(page 3 out of 5)

We ask the same questions every 7 days to a new group of at least 50 participants.

All participants are students who currently reside in the UK. The survey can be taken only once.

In all questions, you will see the percentage of people who picked each answer in the last survey, 7 days ago.

For example, if 65% of participants picked True and 35% picked False, the choices will appear as follows:

True (picked by 65% last week) False (picked by 35% last week)

The following page will explain rewards.

Instructions

(page 3 out of 5)

We ask the same questions every 7 days to a new group of at least 50 participants.

All participants are students who currently reside in the UK. The survey can be taken only once.

In all questions, you will see the percentage of people who picked each answer in the last survey, 7 days ago.

For example, if 65% of participants picked True and 35% picked False, the choices will appear as follows:

True

(picked by 65% last week)

False

(picked by 35% last week)

The following page will explain rewards.

⁹³⁸Instructions

(page 4 out of 5)

You will earn £0.75 for completing the survey.

In addition, you may earn bonus from each question.

Let's see how it works in the example question. Suppose you picked True, as shown below:

True (picked by 65% last week)

False (picked by 35% last week)

At the end of this survey, we calculate the percentage of participants other than you who picked each answer.

You start with £1 bonus. Your bonus increases if the answer you picked is more popular among others in this survey, compared to last week.

Suppose 80% of others picked True this week. Then, you win 80 - 65 = 15 pence from this question.

Suppose 55% of others picked True this week instead. Then, you lose 65 - 55 = 10 pence.

We sum your gains/losses over all questions. Your bonus is never negative and it can increase up to £2.

Your total reward is therefore between £0.75 and £2.75.

Instructions

(page 4 out of 5)

You will earn £0.75 for completing the survey.

In addition, you may earn bonus from each question.

Let's see how it works in the example question. Suppose you picked True, as shown below:

True (picked by 65% last week) False (picked by 35% last week)

At the end of this survey, we calculate the percentage of participants other than you who picked each answer.

You start with £1 bonus. Your bonus increases if the answer you picked is more popular among others in this survey, compared to last week.

Suppose 80% of others picked True this week. Then, you win 80 - 65 = 15 pence from this question.

Suppose 55% of others picked True this week instead. Then, you lose 65 - 55 = 10 pence.

We sum your gains/losses over all questions. Your bonus is never negative and it can increase up to £2.

Your total reward is therefore between £0.75 and £2.75.

Instructions

(page 5 out of 5)

Note that your bonus depends on others' responses.

You earn a higher bonus if you picked answers that became more popular compared to the last survey, which covered the previous 7-day period.

Your own experience may help you guess how others respond.

In the example, say you recall staying too close in a queue at least once.

If keeping distance was more difficult in the last 7 days due to busier streets and shops, ₉₄₀ it is likely that other people experience the same.

Then, you might expect a higher percentage of True picks among others. In that case, picking True increases your bonus.

Remembering your own experiences more accurately can improve your bonus.

949 C Additional results

950 C.1 Study 1

(a) Correlation tests

Draw	Pearson's C.C.	Spearman's C.C.
yellow	r = 0.53, p = 0.118	$\rho = 0.52, p = 0.121$
blue	r = 0.28, p = 0.425	$\rho = 0.21, p = 0.555$
no draw	r = 0.64, p = 0.048	$\rho = 0.68, p = 0.032$

(b) Two-sided t-test and Wilcoxon test

Draw	T-test	Wilcoxon test
yellow	t = 8.56, p < 0.001	W = 100, p < 0.001
blue	t = -8.12, p < 0.001	W = 1, p < 0.001
no draw	t = -0.34, p = 0.739	W = 44, p = 0.676

Table C1: Proportion of left picks vs prior expectation on the number of yellow balls in the actual box.

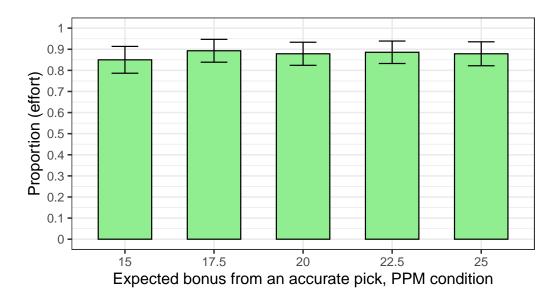

Figure C1: Effort levels in the PPM condition for different levels of the expected bonus from an accurate pick. Error bars show 95% bootstrap CI. See Table A2 for the derivation of expected bonuses.
